We report the genome sequence of *Theileria parva*, an apicomplexan pathogen causing economic losses to smallholder farmers in Africa. The parasite chromosome exhibits limited conservation of gene synteny with *Plasmodium falciparum*, and its plastid-like genome represents the first example where all apicoplast genes are encoded on one DNA strand. We tentatively identify proteins that facilitate parasite segregation during host cell cytokinesis and contribute to persistent infection of transformed host cells. Several biosynthetic pathways are incomplete or absent, suggesting substantial metabolic dependence on the host cell. One protein family that may generate parasite antigenic diversity is not telomere-associated.

*Theileria parva* is a tick-borne parasite that causes a fatal disease in cattle known as East Coast fever (ECF). This disease, which kills over 1 million cattle each year in sub-Saharan Africa, results in economic losses exceeding $200 million annually (1). *Theileria* organisms belong to the phylum Apicomplexa, which has been predicted to have originated about 930 million years ago (2). Unlike other apicomplexans,

The haploid *T. parva* nuclear genome is 8.3 × 10^6 base pairs (Mb) in length and consists of four chromosomes (Table 1). We provide a complete sequence, except for a 1-to-2-kbp gap in chromosome 4 and a gap in chromosome 3 (Tpr locus) that contains a 41-kbp and a 13-kbp set of overlapping sequences (contig) (5). The parasite apicoplast and mitochondrial (6) genomes have also been sequenced. Like *P. falciparum*, *T. parva* chromosomes contain one extremely A+T-rich region (>97%) about 3 kb in length that may be the centromere. The regions between the CCCTA^C tandem repeats and the first protein-encoding gene are short, 2.9 kb on average, and do not contain other repeats. Thus, the structure of the subtelomeric regions in *T. parva* is much less complex than that in *P. falciparum*, where arrays of repeats extend up to 30 kbp (7).

The *T. parva* nuclear genome contains about 4035 protein-encoding genes, 20% fewer than *P. falciparum*, but exhibits higher gene density, a greater proportion of genes with introns, and shorter intergenic regions. There are two identical, unlinked 5.8S-18S-28S rRNA units, suggesting that unlike *P. falciparum*, *T. parva* does not possess functionally distinct ribosomes (8). Putative functions were assigned to 38% of the predicted proteins (Table 1).

The complexity of the *T. parva* life cycle is not matched by a large number of recognizable cell cycle regulators. Thus, the parasite is more akin to yeasts than higher eukaryotes, lacking discernable components of both the p53-MDM2-p14ARF-p21 and the In4-retinoblastoma-E2F pathways (9). There are four predicted cyclins and five cyclin-dependent kinases (cdks), most of which have close homologs in *P. falciparum*. However, *T. parva* lacks one cyclin and two cdks found in *P. falciparum*. These parasite cyclins are poorly conserved (~25% identity), making cross-species comparisons difficult. The reduced recognizable *T. parva* cell cycle machinery suggests that a number of novel regulatory features remain to be discovered.

A unique aspect of *T. parva* biology is that infection of T and B lymphocytes results in a reversible transformed phenotype with uncontrolled proliferation of host cells that remain persistently infected. Parasite proteins that may modulate host cell phenotype are described in an accompanying report (4). Host cell microtubules that decorate the surface of schizonts are captured by the host cell spindle during mitosis, favoring infection of both daughter cells (1). *T. parva* encodes putative secreted forms of EMAP115- and Tau-like proteins, which are absent from *P. falciparum*; in higher eukaryotes, these proteins interact with microtubules (10). In addition, *T. parva* may modulate host cell mitosis by influencing disassembly of the host cell spindle via a secreted cdc48-like AAA–adenosine triphosphatase.
(ATPase associated with diverse cellular activities) (11). A likely \textit{P. falciparum} homolog of this protein contains an N-terminal signal anchor sequence, whereas the \textit{T. parva} protein contains a signal peptide and lacks a recognizable endoplasmic reticulum retention signal.

We used the Tribe-MCL algorithm (5) to identify 384 protein families containing 1063 proteins in the \textit{T. parva} proteome (table S1). The largest family, containing 85 proteins, exists primarily in tandem arrays in the subtelomeric regions of all chromosomes. Many members of the family have a similar architecture, consisting of a secretion signal at the N terminus and a low-complexity glutamine- and proline-rich central domain that may be difficult for vertebrate immune systems to recognize (12). These genes are polymorphic between parasite isolates, and specific genes are absent from certain isolates (13). Each telomere has a conserved \(\sim 140\)-bp sequence immediately adjacent to the telomeric repeat (14), and several subtelomeric regions exhibit 70 to 100% sequence similarity (fig. S1). As in other eukaryotic pathogens, these features may facilitate interchromosomal recombination and the generation of antigenic diversity.

Proteins in the most rapidly evolving \textit{T. parva} protein family, the Tpr (\textit{T. parva} repeat) family, contain complex domain structures reminiscent of a system that has evolved to generate diversity (15). Unlike the majority of hypervariable gene families in parasitic protozoa (16), Tpr sequences are not telomere-associated. This family comprises a tandem array of highly conserved open reading frames (ORFs) on chromosome 3, located \(\sim 570\) kbp from a telomere. The locus, estimated to span 100 kbp, contains at least 28 ORFs, of which 18, ranging in length from 192 to 674 amino acids, lack methionine codons in the first 50 amino acids (fig. S2). Eleven additional dispersed copies of Tpr, also of varying length, contain a 268–amino acid membrane-associated helical domain typical of the Tpr family. Massively parallel signature sequencing (17) and expressed sequence tags suggest that some genes in the locus are only transcribed in the piroplasm stage, whereas at least two of the dispersed genes are transcribed in the schizont stage. In common with the \textit{var} genes of \textit{P. falciparum} (18), domains within the Tpr genes are isolate-specific (19), and the \textit{3’} end of Tpr has been used for genotyping of \textit{T. parva} isolates. Tpr proteins have not yet been detected in piroplasms, and the function of these proteins remains unknown.

The genome sequence provides a global view of the metabolic potential of \textit{T. parva} and allows a comparative analysis with \textit{P. falciparum} metabolism. We predict a reduced functional role for the \textit{T. parva} apicoplast and a greater dependence on the host for many substrates (fig. S3). \textit{T. parva} lacks many enzymes in the shikimic acid, porphyrin, polyamine, and type II fatty acid biosynthetic pathways, but it retains the ability to produce isoprenoids via a methyl erythritol phosphate pathway in the apicoplast. \textit{T. parva} cannot salvage purines, its ability to interconvert amino acids is very limited, and it lacks enzymes that permit the alternative nonoxidative production of pentoses and tetroses via the pentose phosphate pathway. Analysis of predicted transporters revealed fewer transporters of organic nutrients and inorganic cations than are present in \textit{P. falciparum}. However, \textit{T. parva} has more adenosine 5’-triphosphate-binding cassette (ABC) transporters of unknown substrate specificity. Another difference is that \textit{T. parva} encodes an amino acid-cation symporter that is not present in \textit{P. falciparum} (7) or \textit{C. parvum} (20). In contrast to \textit{P. falciparum}, \textit{T. parva} encodes trehalose-6-phosphate synthase and trehalose phosphatase. Trehalose is a disaccharide that plays a role in desiccation and stress tolerance. It may protect the parasite during its long developmental cycle in the tick.

\textit{T. parva} genes encode all of the enzymes necessary for glycolysis, glycerol catabolism, and the tricarboxylic acid (TCA) cycle. Unlike \textit{P. falciparum}, \textit{T. parva} does not encode malate dehydrogenase, but this could be functionally replaced by malate-quinone oxidoreductase, an activity also predicted to be present in \textit{P. falciparum}. The origin of mitochondrial acetyl-coenzyme A (CoA) in both parasites presents a problem, because \textit{P. falciparum} encodes a single pyruvate dehydrogenase that is targeted to the apicoplast (21) and \textit{T. parva} does not encode all the subunits of this enzyme. Both parasites are predicted to contain cytoplasmic acetyl-CoA synthetase and a plasma membrane acetyl-CoA-CoA antiporter, but how mitochondrial oxidation of carbon chains is fueled in these two pathogens remains enigmatic because glycolysis and the tricarboxylic acid cycle do not appear to be linked by a classical route (22). Thus, it is not clear whether the complete TCA cycle is functional. Nitrogen metabolism differs from \textit{P. falciparum} because \textit{T. parva} lacks glutamate-ammonia ligase and only contains a nicotinamide adenine dinucleotide (NAD\(^+\))-dependent glutamate dehydrogenase, which is usually associated with glutamate catabolism. This suggests that imported glutamate could play a role in supplementing intermediates in the TCA cycle.

The ionophores valinomycin and gramicidin D kill \textit{T. parva}, suggesting that a mitochondrial electrochemical gradient is essential for parasite survival (23), but it is not known whether this is coupled to ATP synthesis. All subunits of the F1 catalytic domain of ATP synthase and subunit c of the F0 domain are present, but genes coding for subunits a and b of F0 were not found. The \textit{T. parva} respiratory complexes are similar to those described in \textit{P. falciparum}. Buparvaquone, a hydroxynaphthoquinone drug used in the chemotherapy of ECF, probably inhibits electron transport through complex III (23).

The apicoplast is found in most apicomplexans and plays an essential role in parasite metabolism (24). An A+T-rich, \(\sim 35\)-kbp apicoplast genome encoding 30 proteins, rRNAs, and tRNAs is present in \textit{Plasmodium}, \textit{Toxoplasma}, and \textit{Eimeria}, but not in \textit{Cryptosporidium} (20); the latter lacks an apicoplast. The 39.5-kbp \textit{T. parva} apicoplast genome differs from that of \textit{P. falciparum} in that all of its genes are transcribed in the same direction. In addition, it has one rather than two copies of the rRNA genes, \textit{clpC} is duplicated, the \textit{rpoC2} gene encoding the \(\beta’\) subunit of RNA polymerase is split into two parts, and it lacks the \textit{sufB} gene (Fig. 1). Twenty-six of the \(\sim 44\) \textit{T. parva} apicoplast genome-protein-coding genes share sequence

similarity (27 to 61%) with proteins encoded by the *P. falciparum* apicoplast genome.

Most apicoplast proteins are encoded by nuclear genes and imported into the organelle by means of a bipartite targeting presequence (24). Comparison of the 345 *T. parva* (5) and 551 *P. falciparum* (7) predicted apicoplast-targeted (AT) proteins revealed similarities and differences in apicoplast function. The apicoplasts of *Plasmodium* and *Toxoplasma* participate in heme biosynthesis and are the sites of type II fatty acid and isoprenoid biosynthesis. Apicoplast-derived fatty acids in these parasites might contribute to the establishment and modification of the parasitophorous vacuole membrane (25). It may be notable that both *T. parva* and *T. annulata*, which have only retained isoprenoid biosynthesis, do not exist within a parasitophorous vacuole. About 100 AT proteins were found in both species, but 40% of these were hypothetical proteins, indicating that many core apicoplast functions have yet to be defined.

Fe-S clusters are required in mitochondria and plastids for the maturation of apoproteins. Fe-S cluster formation in the *T. parva* mitochrondrion appears to be similar to that in yeast and *Plasmodium* (26) (table S3). However, of the *sufABCDES* genes involved in the assembly of Fe-S clusters in *Arabidopsis thaliana* (27) and *P. falciparum* plastids (26), only *sufS* was identified in *T. parva*. SufS is a cysteine desulfurase that requires SufE for catalytic activity. The parasite *T. parva* genome encodes a plastid-targeted tRNA thiolation enzyme (MnmA) that has an additional domain similar both in sequence and predicted structure to the sulfur-binding domain of SufE. Thus, a previously unknown complex of SufS/MnmA may catalyze thiolation of tRNA in the *T. parva* apicoplast. The *T. parva* nuclear genome also encodes an AT protein with homology to NFUI, a scaffold protein for Fe-S cluster assembly in *A. thaliana* plastids (26), suggesting that assembly of Fe-S clusters occurs in the *T. parva* apicoplast despite the absence of most Suf proteins.

**T. parva** and *T. annulata* exhibit near-complete synteny across all chromosomes (4). To examine the extent of conservation of gene synteny between the evolutionarily distant *P. falciparum* and *T. parva*, we applied an iterative syntenic block algorithm and Jaccard-filtered COGs to whole-genome data from *P. falciparum* clone 3D7 (7), *P. y. yoelii* (29), *C. parvum* (20), and *T. parva*. Extensive synteny was found between *P. falciparum* and *P. y. yoelii* but not between *P. falciparum* and *C. parvum* or between *T. parva* and *C. parvum*. A total of 435 microsyntenic regions containing 1279 orthologs were observed between *P. falciparum* and *T. parva*, consisting of groups of 2 to 11 orthologs conserved in position between the two genomes (Fig. 2). This may be an underestimate of the degree of microsynteny as it is possible that, due to its long-term in vitro culture, clone 3D7 may represent an atypical genome. Syntenic clusters were distributed uniformly along each chromosome except for the subtelomeric regions, which contain species-specific gene families.
The genome sequence of *T. parva* shows remarkable differences from the other apicomplexan genomes sequenced to date. It provides significant improvements in our understanding of the metabolic capabilities of *T. parva* and a foundation for studying parasite-induced host cell transformation and constitutes a critical knowledge base for a pathogen of significance to agriculture in Africa. Mining of sequence data has already proved useful in the search for candidate vaccine antigens (3).

Long-Term Monitoring of Bacteria Undergoing Programmed Population Control in a Microchemostat

Frederick K. Balagaddé, Lingchong You,†† Carl L. Hansen,§ Frances H. Arnold,∥ Stephen R. Quake*‡

Using an active approach to preventing biofilm formation, we implemented a microfluidic bioreactor that enables long-term culture and monitoring of extremely small populations of bacteria with single-cell resolution. We used this device to observe the dynamics of *Escherichia coli* carrying a synthetic “population control” circuit that regulates cell density through a feedback mechanism based on quorum sensing. The microfluidic bioreactor enabled long-term monitoring of unnatural behavior programmed by the synthetic circuit, which induced sustained oscillations in cell density and associated morphological changes, over hundreds of hours.

By continually substituting a fraction of a bacterial culture with sterile nutrients, the chemostat (1, 2) presents a near-constant environment that is ideal for controlled studies of microbes and microbial communities (3–6). The considerable challenges of maintaining and operating continuous bioreactors, including the requirement for large quantities of growth media and reagents, have pushed the move toward miniaturization and chip-based control (7–10), although efforts have been limited to batch-format operation. Microbial biofilms, which exist in virtually all nutrient-sufficient ecosystems (11), interfere with continuous bioreactor operation (12). Phenotypically distinct from their planktonic counterparts (11), biofilm cells shed their progeny into the bulk culture and create mixed cultures. At high dilution rates, the biofilm, which is not subject to wash-out, supplies most of the bulk-culture cells (13). The increase in surface area-to-volume ratio as the working volume is decreased aggravates these wall-growth effects (13).

We created a chip-based bioreactor that uses microfluidic plumbing networks to actively prevent biofilm formation. This device allows semicontinuous, planktonic growth in six independent 16-nanoliter reactors with no observable wall growth (Fig. 1A). The cultures can be monitored in situ by optical microscopy to provide automated, real-time, noninvasive measurement of cell density and morphology with single-cell resolution.

Each reactor, or “microchemostat,” consists of a growth chamber, which is a fluidic loop 10 μm high, 140 μm wide, and 11.5 mm in circumference, with an integrated peristaltic pump and a series of micromechanical valves to add medium, remove waste, and recover cells (Fig. 1B). The growth loop is itself composed of 16 individually addressable segments. The microchemostat is operated in one of two alternating states: (i) continuous circulation, and (ii) cleaning and dilution. During continuous circulation, the peristaltic pump moves the microculture around the growth loop at a linear velocity of ~250 μm s⁻¹ (Fig. 1C). During cleaning and dilution, the mixing is halted and a segment is isolated from the rest of the reactor with micromechanical valves. A lysis buffer is flushed through the isolated segment for 50 s to expel the cells it contains, including any wall-adhering cells (Fig. 1D). Next, the segment is flushed with sterile growth medium to completely rinse out the lysis buffer. This segment, filled with sterile medium, is then reunited with the rest of the growth chamber, at which point continuous circulation resumes. This process is repeated sequentially on different growth chamber segments, thus eliminating biofilm formation and enabling pseudocontinuous operation. In comparison, passive treatment of the microfluidic surfaces with nonadhesive surface coatings [such as poly (ethylene glycol), ethylenediaminetetraacetic acid, polyoxyethylene sorbitan monolaurate, and bovine serum albumin] proved ineffective in preventing biofilm formation.
