The condensin complex is a mechanochemical motor that translocates along DNA

Condensin plays crucial roles in chromosome organization and compaction, but the mechanistic basis for its functions remains obscure. We used single-molecule imaging to demonstrate that *Saccharomyces cerevisiae* condensin is a molecular motor capable of adenine triphosphate hydrolysis–dependent translocation along double-stranded DNA. Condensin’s translocation activity is rapid and highly processive, with individual complexes traveling an average distance of ≥10 kilobases at a velocity of ~60 base pairs per second. Our results suggest that condensin may take steps comparable in length to its ~50-nanometer coiled-coil subunits, indicative of a translocation mechanism that is distinct from any reported for a DNA motor protein. The finding that condensin is a mechanochemical motor has important implications for understanding the mechanisms of chromosome organization and condensation.

Structural maintenance of chromosomes (SMC) complexes are the major organizers of chromosomes in all living organisms (1, 2). These protein complexes play essential roles in sister chromatid cohesion, chromosome condensation and segregation, DNA replication, DNA damage repair, and gene expression. A distinguishing feature of SMC complexes is their large ring-like configuration, the circumference of which is made up of two SMC coiled-coil subunits and a single kleisin subunit (Fig. 1A) (1–4). The ~50-nm-long antiparallel coiled-coil subunits are connected at one end by a stable dimerization interface, referred to as the hinge domain, and at the other end by globular adenine triphosphatase (ATPase) domains belonging to the ATP-binding cassette family (5). The ATPase domains are bound by a protein of the kleisin family, along with additional accessory subunits, which vary for different types of SMC complexes (Fig. 1A). The relationship between SMC structures and their functions in chromosome organization is not completely understood (6), but many models envision that the coiled-coil domains allow the complexes to topologically embrace DNA (1–4). Given the general resemblance to myosin and kinesin, some early models postulated that SMC proteins might be mechanicomochemical motors (7–10).

SMC complexes are thought to regulate genome architecture by physically linking distal chromosomal loci, but how these bridging interactions might be established is unknown (1, 2, 11). An early model suggested that many three-dimensional (3D) features of eukaryotic chromosomes might be explained by DNA loop extrusion (Fig. 1B) (12, 13), and recent polymer dynamics simulations have shown that loop extrusion can recapitulate the formation of topologically associating domains, chromatin compaction, and sister chromatid segregation (14–18). This loop extrusion model assumes a central role for SMC complexes in actively creating the DNA loops (11, 12). Similarly, it has been proposed that prokaryotic SMC proteins may structure bacterial chromosomes through an active loop extrusion mechanism (19–21). However, the loop extrusion model remains hypothetical, in large part because the motor activity that is necessary for driving loop extrusion could not be identified (11). The absence of an identifiable motor activity in SMC complexes instead has lent support to alternative models in which DNA loops are not actively extruded but rather are captured and stabilized by stochastic pairwise SMC binding interactions to bridge distal loci (22).

To help distinguish between possible mechanisms of SMC protein–mediated chromosomal organization, we examined the DNA binding properties of condensin (23). We overexpressed the five subunits of the condensin complex in budding yeast and purified the complex to homogeneity (Fig. 1C and fig. S1). Electron microscopy images confirmed that the complexes were monodisperse (Fig. 1D). As previously described for electron micrographs of immunopurified *Xenopus laevis* or human condensin (24), we observed electron density that presumably corresponds to the two HEAT-repeat subunits in close vicinity to the Smc2-Smc4 ATPase head domains. We confirmed that the *Saccharomyces cerevisiae* condensin holocomplex binds double-stranded DNA (dsDNA) and hydrolyzes ATP in vitro (Fig. 1, E and F). Addition of dsDNA stimulated the condensin ATPase activity so that it increased about threefold, which is consistent with previous measurements with *X. laevis* condensin I complexes (25). We found a Michaelis constant (*Km*) and catalytic rate constant (*kcat*) of 0.4 ± 0.07 mM and 2.0 ± 0.1 s⁻¹, respectively (means ± SE), for ATP hydrolysis in the presence of linear dsDNA (Fig. 1G). Furthermore, condensin promoted extensive ATP hydrolysis–dependent DNA compaction of single-tethered DNA curtains, which was reversible by increasing the salt concentration to 0.5 M NaCl (fig. S2, A to C). An ATPase-deficient version of condensin with mutations in the γ-phosphate switch loops (Q-loops) of SMC2 and SMC4 still bound DNA (Fig. 1E) but exhibited no ATP hydrolysis activity (Fig. 1F) or DNA compaction activity (fig. S2D).

We then used total internal reflection fluorescence microscopy to visualize binding of single fluorescently tagged condensin holocomplexes to double-tethered DNA substrates (26). We fluorescently labeled condensin with quantum dots (Qdots) conjugated to antibodies against triple copies of the hemagglutinin (HA) tag fused to the Brn1 kleisin subunit (Fig. 1A). Electrophoretic mobility shift assays confirmed that condensin was quantitatively labeled (fig. S3A). Importantly, binding to the Qdots inhibited neither condensin’s ATP hydrolysis activity nor its ability to alter DNA topology (fig. S3, B and C). We prepared double-tethered curtains by attaching the DNA substrates (~48.5-kb λ-DNA) to a supported lipid bilayer through a biotin-streptavidin linkage; we then aligned one end of the DNA molecules at nanofabricated chromium (Cr) barriers and anchored the other end to Cr pedestals located 12 μm downstream (Fig. 2A) (26).

Using double-tethered curtains, we were able to detect binding of condensin complexes to individual DNA molecules (Fig. 2B). Although we observed single Qdot-tagged condensin complexes, we do not yet know whether the observed complexes were single condensin molecules or condensin oligomers. Kymographs revealed that ~85% of all bound condensin complexes (n = 671) underwent linear motion along the DNA (Fig. 2C and movie S1). The up or down direction of movement was random, but once a complex started to translocate, it generally proceeded unidirectionally without a reversal of direction (reversals were observed occasionally, in 6% of the traces). Condensin has not been previously shown to act as a molecular motor, but the observed movement is fully consistent with expectations for ATP-dependent translocation of a motor protein along DNA. Unlike the wild-type condensin, the ATPase-deficient Q-loop mutant of condensin only exhibited motion consistent with random 1D diffusion (Fig. 2D). Wild-type condensin in the presence of the nonhydrolyzable ATP analog ATP[S] also displayed only 1D diffusion (fig. S4A). Previous single-molecule experiments demonstrated rapid 1D diffusion of cohesin on DNA but found no evidence for ATP-dependent translocation, suggesting that there may be differences in how the two SMC complexes process DNA (27, 28).
Fig. 1. Biochemistry of budding yeast condensin holocomplexes. (A) Schematic of the S. cerevisiae condensin complex. The Brn1 kleisin subunit connects the ATPase head domains of the Smc2-Smc4 heterodimer and recruits the HEAT-repeat subunits Ycs4 and Ycg1. The cartoon highlights the position of the HA3 tag used for labeling. (B) Conceptual schematic of loop extrusion for models with either two (top) or one (bottom) DNA strand(s) passing through the center of the SMC ring. (C) Wild-type and ATPase-deficient Smc2(Q147L)-Smc4(Q302L) condensin complexes analyzed by SDS–polyacrylamide gel electrophoresis and Coomassie staining (Q, glutamine; L, leucine). (D) Electron micrographs of wild-type condensin holocomplexes rotary-shadowed with platinum/carbon. Scale bars, 100 nm. (E) Electrophoretic mobility shift assays with a 6-carboxyfluorescein–labeled 45-bp dsDNA substrate (100 nM) and the indicated protein concentrations. (F) ATP hydrolysis by wild-type and ATPase-deficient condensin complexes (0.5 μM) upon addition of increasing concentrations of a 6.4-kb linear DNA at saturated ATP concentrations (5 mM). The plot shows means ± SD from three (wild-type) or two (ATPase mutant) independent experiments. (G) Michaelis-Menten kinetics for the rate of ATP hydrolysis by wild-type condensin complexes (0.5 μM) at increasing ATP concentrations in the presence of 240 nM 6.4-kb linear DNA. The plot shows means ± SD from three independent experiments. The fit corresponds to a $K_m$ of 0.4 ± 0.07 mM for ATP and a $k_{cat}$ of 2.0 ± 0.1 s$^{-1}$ per molecule of condensin (mean ± SE).

Fig. 2. DNA curtain assay for DNA binding activity of condensin. (A) Schematic of the double-tethered DNA curtain assay (up and down arrows, inlet and outlet of buffer, respectively). (B) Still images showing Qdot-tagged condensin (magenta) bound to YoYol-stained DNA (green). (C) Kymograph showing examples of Qdot-tagged condensin translocating on a single DNA molecule (unlabeled); the initial condensin binding sites, dissociation positions, and collisions with the barriers or pedestals are highlighted with color-coded arrowheads. (D) Kymograph showing Qdot-tagged ATPase-deficient mutant Smc2(Q147L)-Smc4(Q302L) condensin undergoing 1D diffusion on DNA (unlabeled). (E) Initial binding site and (F) dissociation site distributions of condensin superimposed on the A/T content of the λ-DNA substrate. All reactions contained 4 mM ATP. Error bars in (E) and (F) represent SD calculated by boot strap analysis. kbp, kilobase pairs.
rather, 52% (255/491) of the complexes went one direction, and 48% (236/491) went the opposite direction. The condensin ATPase mutant did not exhibit any evidence of unidirectional translocation. Mean squared displacement (MSD) plots generated from condensin tracking data exhibited increasing slopes (Fig. 3C), which is only consistent with directed motion (29). In contrast, MSD plots were linear for the ATPase-deficient condensin mutant (Fig. 3D) and for wild-type condensin in the presence of ATPγS (fig. S4C). Linear MSD plots were characteristic of random diffusive motion (29), yielding diffusion coefficients of (1.7 ± 1.4) × 10−3 (0.8 ± 1.0) × 10−3 μm² s−1 (means ± SD) for ATPase-deficient condensin and wild-type condensin plus ATPγS, respectively.

We used the tracking data to determine the velocity and processivity of wild-type condensin. A plot of the velocity distributions for data collected in the presence of saturated concentrations of ATP (4 mM; Fig. 1G) was well described by a log-normal distribution, revealing a mean apparent translocation velocity of 63 ± 36 base pairs (bp) s−1 (16 ± 9 nm s−1; means ± SD; n = 491) (Fig. 3E). Upon initial binding, condensin paused for a brief period (τpause = 13.3 ± 1.5 s; mean ± SD) before beginning to move along the DNA, which suggests the existence of a rate-limiting step before condensin becomes active for translocation (Fig. 2C and fig. S5). Each translocating condensin complex remained bound to the DNA for an average total time of 4.7 ± 0.2 min and traveled an average of 10.3 ± 0.4 kb (2.6 ± 0.1 μm; means ± SD) before dissociating (Fig. 3F and fig. S6A). These values provide merely a lower limit of the processivity of condensin, because a considerable fraction (42%) of the complexes traveled all the way to the ends of the 48.5-kb λ-DNA, where they collided with the Cr barriers or pedestals (for example, Fig. 2C). There was no correlation between translocation velocity and processivity at a given ATP concentration (Pearson’s r = 0.035, P = 0.43 at 4 mM ATP) (fig. S6B). However, velocity and processivity both varied with ATP concentrations. From Michaelis-Menten analysis, we found a maximum velocity of 62 ± 2 bp s−1 and a Kₘ of 0.2 ± 0.04 mM ATP (means ± SD) (fig. S7, A and B). The initial pause time (τpause) also varied with ATP concentration, from 3.9 ± 0.8 min at 50 μM ATP to 13.3 ± 1.5 s at 4 mM ATP (means ± SD), suggesting that this delay reflects a transition from a translocation-inactive to a translocation-active state that is dependent on ATP binding, ATP hydrolysis, or both (fig. S7C). Our finding that condensin is an ATP hydrolysis-dependent molecular motor lends support to models invoking SMC protein–mediated loop extrusion as a means for 3D genome organization. An important prediction of the loop extrusion model is that condensin must simultaneously interact with two distal regions of the same chromosome, and at least one (or possibly both) of the interaction sites must translocate away from the other site, allowing for movement of the two contact points relative to one another (Fig. 4A) (12, 14–17). Such “cis” loop geometry is inaccessible in our double-tethered assays because the DNA is held in an extended configuration (Fig. 2A), which likely decouples loop extrusion from translocation. However, a cis loop configuration can be mimicked experimentally by providing a second DNA molecule in trans (fig. 4B) to test the possible relationship between the observed linear translocation of condensin along the double-tethered DNA and the loop extrusion model, we asked whether condensin could move a second DNA substrate provided in trans relative to the tethered DNA. Indeed, fluorescently labeled (not extended) λ-DNA molecules added in trans to wild-type condensin moved at an apparent velocity of 76 ± 19 bp s−1 (19 ± 5 nm s−1; n = 102) (Fig. 4, C and D; movie S2; and data S2) while traveling an average distance of 11 ± 0.9 kb (2.7 ± 0.2 μm; means ± SD; n = 102) (Fig. 4E)—numbers that match well with the measured condensin motor properties reported above. These experiments strongly indicate that...
translocating condensin complexes were able to interact simultaneously with the tethered DNA and a second DNA. Also, condensin could translocate while bound to both DNA substrates, given that one piece of DNA was observed to move with respect to the other piece of DNA. Thus, we conclude that condensin is capable of moving two DNA substrates relative to one another, fulfilling a key expectation of the loop extrusion model.

Heretofore, a common argument against SMC proteins acting as molecular motors was their low rates of ATP hydrolysis relative to other known nucleic acid motor proteins, which implied that they would not move fast enough to function as efficient motors on biologically relevant time scales. However, this discrepancy can be readily reconciled if condensin is able to take large steps, which is conceptually possible given its large size of >50 nm. The available data, in fact, suggest a large step size: Comparison of the single complex translocation rate (~60 bp s\(^{-1}\), or ~14.9 nm s\(^{-1}\)) with the bulk rate of ATP hydrolysis (\(k_{\text{cat}} = 2.0\) s\(^{-1}\) in the presence of linear DNA) indicates that condensin may take steps on the order of ~30 bp per molecule of ATP hydrolyzed. Even larger steps can be inferred if each step is coupled to the hydrolysis of more than one molecule of ATP. These estimates assume that all of the proteins are ATPase-active (one would deduce a smaller step size if a fraction of the protein were inactive) and also assume perfect coupling between ATP hydrolysis and translocation (whereas a more inefficient coupling would necessitate even larger step sizes). The idea that condensin takes very large steps is consistent with the step sizes reported from magnetic tweezer experiments examining DNA compaction induced by X. laevis condensin [80 ± 40 nm; mean ± SD (30)] or S. cerevisiae condensin (31). Such large step sizes would seem to rule out models of movement for condensin that resemble those for common DNA motor proteins such as helicases, translocases, or polymerases, which are typically found to move in 1-bp increments (32–35). Higher-resolution measurements may prove informative for further defining the fundamental step size of translocating condensin.

To explain our results, we searched for possible models for condensin motor activity that (i) can explain the relationship between a slow ATP hydrolysis rate relative to the rate of translocation, (ii) can accommodate a very large step size, and (iii) are consistent with the physical dimensions of the SMC complex. Given these criteria, we can think of two theoretical possibilities, both of which use the SMC coiled-coil domains as the means of motion. Condensin might translocate along DNA through reiterative extension and retraction of the long Smc2-Smc4 coiled-coil domains, allowing for movement through a “scrunching” mechanism involving rod- to butterfly-like structural transitions (Fig. 4F); alternatively, condensin may use a myosin- or kinesin-like “walking” mechanism (Fig. 4G). The maximum single step size for each model is defined by the physical dimensions of the SMC coiled-coil domains, corresponding to ≤50 and ≤100 nm for the scrunching and walking mechanisms, respectively (Fig. 4, F and G). Both models are consistent with the range of condensin architectures observed by electron and atomic force microscopy (24, 30). Movements might be powered by ATPase-dependent transitions between different structural states similar to those reported for prokaryotic SMC complexes (21, 37, 38), although it remains to be determined how conformational changes could be translated into the directed movement depicted in our models. Further refinement of the translocation mechanism will depend on fully defining the structural transitions that take place during the ATP hydrolysis cycle and establishing a better understanding of whether (and if so, how) different domains in the condensin complex engage DNA.

Recent Hi-C studies have shown that condensin-dependent DNA juxtaposition occurs at an apparent rate of ~900 bp s\(^{-1}\) in Bacillus subtilis.
DNA did not find evidence for translocation on SMC complexes that seemingly lack motor activity. The finding that condensin is expected to translocate along DNA at a rate of ~30 bp s⁻¹ suggests that the ATP hydrolysis of condensin expression constructs; D. Condensin is a highly processive DNA motor
Condensin is thought to regulate genome architecture by creating DNA loops. Terakawa et al. used single-molecule imaging to show that yeast condensin is a highly processive mechanochemical motor capable of translocating along DNA (see the Perspective by Nasmyth). Their findings elucidate how the rapid ATP hydrolysis–dependent motor activity of condensin provides the driving forces necessary to support three-dimensional chromosome organization and compaction through a loop extrusion mechanism.
