Bacteria were first detected in human tumors more than 100 years ago, but the characterization of the tumor microbiome has remained challenging because of its low biomass. We undertook a comprehensive analysis of the tumor microbiome, studying 1526 tumors and their adjacent normal tissues across seven cancer types, including breast, lung, ovary, pancreas, melanoma, bone, and brain tumors. We found that each tumor type has a distinct microbiome composition and that breast cancer has a particularly rich and diverse microbiome. The intratumor bacteria are mostly intracellular and are present in both cancer and immune cells. We also noted correlations between intratumor bacteria or their predicted functions with tumor types and subtypes, patients’ smoking status, and the response to immunotherapy.

More than 16% of cancer incidence worldwide has been attributed to infectious agents (1). Intratumor bacteria have been reported in many tumor types (2–19), but these bacteria have not been characterized in a comprehensive manner (20). The gut microbiome has been shown to have multiple effects on tumor biology, such as the transformation process, tumor progression, and the response to anticancer therapies including immunotherapy (21–29). Thus, characterization of the tumor microbiome may be an essential step in unraveling the effects that tumor bacteria have on cancer history. We undertook an extensive combination of methods to characterize and visualize intratumor bacteria, we applied an extensive combination of methods to a large cohort of solid human tumor samples with bacteria or bacterial DNA can be problematic (30, 31). Therefore, it is critical to include multiple measures to avoid, or at least detect, any possible contamination in the process of profiling the tumor microbiome (supplementary note) (32, 33). For next-generation sequencing applications, it is also important to use mechanical tissue shearing in the DNA isolation protocol to ensure the complete recovery of DNA from within the cell wall of Gram-positive bacteria—a step not included in most standard DNA isolation protocols (6, 7). To characterize and visualize intratumor bacteria, we applied an extensive combination of methods to a large cohort of solid human tumor samples to detect bacterial DNA, RNA, and bacterial outer membrane or cell wall components. We focused on seven solid tumor types that represent either common cancer types or cancer types for which the tumor microbiome is largely unknown, such as melanoma, bone, and brain tumors (Fig. 1A). To address laboratory-borne contaminants, we introduced 643 negative controls that were processed with the samples, including 437 DNA extraction controls and 206 polymerase chain reaction (PCR) no-template controls (NTCs). To address contamination that might have occurred before the samples reached our laboratory, we also included 168 paraffin-only samples taken from the margins of the paraffin blocks (without tissue) that were used in the study (Fig. 1A).

Overall, we profiled 1010 tumor samples and 516 normal samples, including normal adjacent tissues (NATs) from the same patients (Fig. 1A and table S1). In the case of ovarian cancer, our normal samples came from the ovaries or uteruses of the patients or from normal fallopian tube fimbria of unmatched healthy subjects (tables S1 and S2). To quantify bacterial DNA, we used a real-time quantitative PCR (qPCR) assay with universal primers 967F and 1064R specific for the bacterial ribosomal 16S gene [16S rDNA (ribosomal DNA)] (34). Levels of bacterial DNA in all tumor types were significantly higher than those found in both DNA extraction and paraffin controls (Fig. 1B; P value <10−10 for each tumor type, Wilcoxon rank sum test). We found that different cancer types vary in the proportion of tumors that are positive for bacterial DNA, ranging from only 14.3% in melanoma to >60% in breast, pancreatic, and bone tumors. Bacterial DNA was also detected in solid tumors that have no direct connection with the external environment, such as ovarian cancer, glioblastoma multiforme (GBM), and bone cancer.

To validate the presence of bacteria in human tumors, we stained >400 additional tumors (not related to the 1526 samples described above), representing six of our seven profiled tumor types, for the presence of bacteria. We conducted immunohistochemistry (IHC) using antibodies against bacterial lipopolysaccharide (LPS) and lipoteichoic acid (LTA) to detect Gram-negative and Gram-positive bacteria, respectively (35, 36). We also used RNA fluorescence in situ hybridization (FISH), with a

universal probe against bacterial 16S ribosomal RNA (rRNA), to detect bacterial RNA in these tumors (37). To control for nonspecific staining, IHC-negative controls (no primary antibody) and FISH-negative controls (nonspecific complement probe) were also applied to the samples (figs. S1 and S2). Bacterial LPS and 16S rRNA were frequently detected in all tumor types (Fig. IC) and demonstrated a similar spatial distribution (Fig. 1D and fig. S3). LTA was detected mainly in melanomas and was largely absent in other tumor types.

Generally, more tumors were found to be positive for bacteria using visualization methods than by using qPCR. This disparity may be because of some limitation in the sensitivity of our qPCR assay, or it might be caused by our strict cutoff for confirming a sample as positive.

**Intratumor bacteria are mostly intracellular and are present in both cancer and immune cells**

Pathological examination of tumor cores indicated that LPS and bacterial 16S rRNA were localized mainly in cancer cells and immune cells (Fig. 2A and fig. S4). In cancer cells, bacterial 16S rRNA was detected mostly in the cytoplasm, whereas LPS staining was associated with both the cytoplasm and the nucleus (Fig. 2B and fig. S5). CD45-positive leukocytes generally exhibited a stronger cytoplasmic bacterial staining by 16S rRNA staining than that exhibited by cancer cells (Fig. 2C and fig. S6A). LTA-positive bacteria were almost exclusively found in macrophages, as detected by hematoxylin and eosin (H&E) staining and verified by immunofluorescence (IF) for CD68 (Fig. 2D and fig. S6B). LTA was rarely detected in cancer cells or in CD45+/CD68− immune cells (Fig. 2). Although the intensity of bacterial LPS and LTA staining was very strong in CD45+/CD68+ cells, bacterial 16S rRNA was only rarely found in macrophages by FISH (Fig. 2, A and D, and figs. S4 and S6). This discrepancy may reflect macrophage ingestion of bacterial components rather than live bacteria, or it may result from the accumulation of LPS and LTA in macrophages long after the bacteria have been phagocytosed and processed by the macrophages. It has been previously demonstrated that the processing of bacterial LPS by macrophages is very slow; therefore, LPS can be found in these cells months after the bacteria were ingested and processed (38).

To further verify the presence of bacteria inside cancer cells, we performed correlational light and electron microscopy (CLEM) (39, 40) on four human breast tumors that were positive for bacterial LPS and 16S rRNA (fig. S7). Combined LPS fluorescence staining and transmission electron microscopy (TEM) imaging of the same cells clearly demonstrated the intracellular localization of bacteria in all four tumors (Fig. 2E and fig. S7). In many cases, the bacteria were found in close proximity to the nuclear membrane. Because we did not detect intranuclear bacteria by TEM, we suspect that the appearance of LPS nuclear localization in some tumors represents the staining of cytoplasmic peri-nuclear bacteria.

Whereas bacterial 16S rRNA FISH staining appeared as a diffused signal inside cells, typical bacterial rods or cocci were only rarely detected (in 3 of 426 cores). This observation, combined with the fact that no cell wall polymer LTA was detected in cancer cells—despite the detection of many Gram-positive bacteria in human tumors by 16S rDNA sequencing—suggests that bacteria in tumor cells may have altered their envelope, perhaps leading to a cell wall–deficient state, akin to L-forms (41). Cell wall–deficient bacteria are known to be found exclusively inside cells, where their morphology transforms into less-defined structures of highly variable sizes and shapes (42, 43). Our TEM images also suggest that many of the
Intratumor bacteria are found inside both cancer and immune cells. (A) Summary of the staining patterns of LPS, LTA, and bacterial 16S rRNA in different cell types across 459, 427, and 354 tumor cores, respectively. CD45+/CD68+ cells are referred to as macrophages; CD45+/CD68− cells are referred to as other immune cells. (B to D) Representative cores are shown demonstrating the different staining patterns in human tumors. Asterisks mark the region that was selected for higher magnification. (B) Bacterial LPS and 16S rRNA are demonstrated in breast cancer cells. (C) Bacterial LPS and 16S rRNA are demonstrated in CD45+/CD68− cells of a highly inflamed breast tumor. (D) A melanoma tumor demonstrating typical staining of macrophage-associated bacteria (M), with positive LPS and LTA staining but no 16S rRNA staining. Nearby tumor cells (T) show the typical LPS and 16S rRNA staining, with negative LTA staining. Each inset demonstrates a low magnification of the entire core. Scale bars in high-magnification images, 20 μm. (E) CLEM demonstrates intracellular bacteria in human breast cancer. IF image shows DAPI in blue and LPS in red. Two bacteria are marked with arrows. TEM images of the same cell are shown in grayscale. High-magnification image of the boxed area is shown on the right. The letter N marks the cell nucleus.

The microbiome of breast tumors is richer and more diverse than that of other tumor types

To characterize the intratumor microbiome, we developed a multiplexed 16S rDNA sequencing protocol that amplifies five short regions along the 16S rRNA gene: the 5R, 16S rRNA sequencing method (Fig. 3A). By amplifying 68% of the bacterial 16S rRNA gene using short amplicons, this method increases the coverage and resolution of the detection of bacterial species compared with the widely used V4 or V3-V4 amplification (fig. S8). Moreover, it can be applied to partially degraded DNA originating from formalin-fixed paraffin-embedded tumors. Reads from 1526 samples and 811 negative controls (DNA extraction controls, 16S rDNA sequencing, 5R PCR controls, and paraffin controls) were computationally combined into long amplicons, using Short MUltiple Regions Framework (SMURF) (44) and the Greengenes database as a reference. To improve taxonomic assignment, we used the Ribosomal Database Project (RDP) classifier to augment the Greengenes database by assigning a species-level taxonomy to 380,000 bacterial 16S rRNA sequences that originally lacked such taxonomy (45) (table S3 and materials and methods). Thirty-nine samples and 10 controls that had fewer than 1000 normalized reads were discarded from further analysis (materials and methods).

Overall, we detected 9190 bacterial species across the different tumor or normal tissue types (Fig. 3B and table S2). Because some of these species may represent contamination of the samples, we applied a strict set of six filters to control for potential sources of contamination. To account for the most frequent general contaminants, filter 1 removed 167 bacterial species that were detected in >7.5% of our DNA extraction and NTC negative control samples or in the paraffin controls. This threshold demarcates the transition between most of the species that are absent or very rarely present in controls and the species that appear much more commonly in controls (fig. S9). We then applied three filters to control for batch effects that originate from DNA extraction, PCR amplification, or sequencing lane using hundreds of negative controls as a background for laboratory-borne contamination (filters 2 to 4). Filters 5 and 6 were added to control for contamination that might have been introduced to the samples before their processing in the laboratory. Filter 5 uses paraffin-only samples (without tissue) from the margins of the same paraffin blocks that were used in the study to control for contamination in the process of preparing and storing the paraffin blocks. Lastly, to account for other potential sources of medical center-specific contamination, filter 6 excluded bacteria that were not significantly enriched in a specific tumor type across multiple medical centers. Only bacteria that passed all six filters in a specific cancer type or its NAT were considered to be hits that are present in this cancer or NAT condition (Fig. 3B, table S4, materials and methods, and supplementary note).

We found that breast tumors had a richer and more diverse microbiome than all other tumor types tested (P value <10−15 for each tumor type, Wilcoxon rank sum test; Fig. 3, C and D, and figs. S10 and S11). An average of 16.4 bacterial species were detected in any single breast tumor sample, whereas the average was <9 in all other tumor types (P value <10−15 for each tumor type, Wilcoxon rank sum test; Fig. 3E and fig. S11). We also found that bacterial load and richness were higher in the breast tumor samples than those found in normal breast samples from healthy subjects.
Tumor-adjacent normal breast tissue had an intermediate bacterial load and richness, between those of the breast tumor and normal samples (Fig. 3F and fig. S12). In contrast, we did not find a higher bacterial load in lung and ovarian tumors compared with their tumor-adjacent normal tissues (fig. S12).

To determine whether live bacteria are present in human tumors, we collected fresh breast tumor samples from five women undergoing breast surgery. All tissues were gently dissociated in sterile conditions, plated on 35 types of agar growth media, and incubated under both aerobic and anaerobic conditions, representing a broad span of growth conditions to accommodate a high diversity of bacteria (table S5). In agreement with the positive staining of these tumors for LPS and 16S rRNA FISH (fig. S13), >1000 colonies were grown per tumor from four of the tumors, and 37 colonies were grown from one tumor. In contrast, applying the same steps of tissue dissociation and culturing protocol to five full sets of negative control plates (350 plates) using only phosphate-buffered saline (PBS) yielded only five colonies in total. Whole-genome sequencing of 474 representative colonies from all five tumors demonstrated that they represented 37 different bacterial species, 11 of which (29.7%) are bacteria that were previously detected as hits in our breast tumor cohort (table S5). Fifteen isolated species (40.5%) were detected in our breast tumor cohort but did not pass all filters. For 105 of the colonies, we could not identify the bacteria at the species level (table S5 and materials and methods).

Overall, these results show that live bacteria from three main phyla—Proteobacteria, Firmicutes, and Actinobacteria—can be found in breast tumors.

To further validate the presence of live, metabolically active bacteria in human tumors, we cultured slices from four freshly resected human breast tumors ex vivo in the presence of fluorescently labeled D-alanine or dimethyl sulfoxide (DMSO) control. Although D-alanine is used by bacteria to generate peptidoglycan, an essential component of the bacterial cell wall, it is not used by mammalian cells (fig. S14). We detected intracellular labeling in all four tumors, which supports the hypothesis that the tumors harbor live intracellular bacteria (Fig. 3G).

Different tumor types have distinct microbial compositions

Using a single sequencing methodology and platform for the characterization of the microbiome in multiple tumor types enabled us to directly compare the microbiomes of these tumors. Comparison of the beta-diversity between all pairs of samples within a given
The direction of the bars indicates the enrichment direction. All bacteria presented had a false discovery rate (FDR) specific tissue type were considered. Tumor types and their normal tissue are grouped. (Fig. 3F and fig. S16). We added 22 colorectal tumors from one medical center to our cohort to help relate some of our findings to the known colorectal cancer microbiome (table S2) (11, 12). Consistent with previous reports, bacteria belonging to the Firmicutes and Bacteroidetes phyla were the most abundant species in colorectal tumors (Fig. 4B) (10). In contrast, Proteobacteria dominated the microbiome of pancreatic cancer, similarly to the normal duodenal microbiome makeup (16, 17, 48, 49). This may reflect a retrograde bacterial migration from the duodenum, to which the pancreatic duct opens, as we have previously reported (16). Although species belonging to the Proteobacteria and Firmicutes phyla accounted for most of the detected bacterial sequences in all cancer types, the Proteobacteria to Firmicutes (P/F) ratio appears to vary between tumor types (Fig. 4B). We also detected taxa of the Actinobacteria phylum, including the Corynebacteriaceae and Micrococaceae families, mostly in nongastrointestinal tumors (Fig. 4B and fig. S16). These observations are in agreement with previous reports describing the microbiome of breast, lung, and ovarian cancer (2, 4, 6, 9, 14, 15, 18).

A tumor-type distinctive microbiome composition was also apparent at the species level. Unsupervised clustering of the most prevalent intratumor bacterial species (n = 137 species) demonstrated that many of these species are enriched in certain tumor types (Fig. 4, C and D, and fig. S17). *Fusobacterium nucleatum*, previously reported to be enriched in colorectal tumors, was also a hit in our breast and pancreatic tumor cohorts (fig. S17). We also observed a distinct microbiome across subtypes of the same tumor type. For example, when comparing different subtypes of breast cancer according to their estrogen receptor (ER), progesterone receptor (PR), and HER2 status, we found multiple bacterial taxa whose prevalence was different between the subtypes (Fig. 4E and table S6). Lastly, although the overall microbial composition of the different tumor types was relatively similar to their NAT microbiome (Fig. 4F), we also detected bacteria with a different prevalence in tumors and in their NAT (Fig. 4G and table S7). Consistent with our observation that bacterial load and richness of breast tumors are higher than those in breast NAT (Fig. 3F and fig. S12), we found many bacteria that are significantly enriched in breast tumors compared with their NAT (Fig. 4G).

**Fig. 4. Different tumor types have distinct microbial compositions.** (A) Jaccard similarity indexes were computed on the basis of profiles of bacterial species that passed all filters in tumors (n = 528) between all possible pairs of samples. The heatmap presents the average of all indexes between sample pairs from any two cancer types. (B) Distribution of order-level phylotypes across different tumor types. Relative abundances were calculated by summing up the reads of species that passed all filters in the different tumor types and belong to the same order. Orders are colored according to their associated phylum. (C) Unsupervised hierarchical clustering of the prevalence of 137 bacteria species that were hits in one of the tumor types and are present in 10% or more of the samples in at least one of the tumor types. (D) The prevalence of 19 bacteria from (C), displayed across the different tumor types. Only bacteria that are a hit in a given tumor type are represented with colored circles. Circle size indicates the prevalence level in samples. US, unknown species. (E) Bacterial taxa with a significant differential prevalence between different breast tumor subtypes are presented in a bar plot. P values were calculated using a two-sample proportion z test to compare between HER2+ (n = 61) and HER2− (n = 247), ER+ (n = 270) and ER− (n = 49), or triple negative (TN) (n = 36) and non-TNG (n = 284) breast tumors. The direction of the bars indicates the enrichment direction. All bacteria presented had a false discovery rate (FDR)–corrected Q value <0.25. US, unknown species; UG, unknown genus; UF, unknown family; (g), species; (s), genus; (f), family; (c), class. (F) Principal coordinate analysis (PCoA) biplot on the Jaccard similarity indexes between bacterial species profiles of the different tissue types. Only bacteria that passed all filters for the specific tissue type were considered. Tumor types and their normal tissue are grouped. (G) Volcano plot demonstrating the differential prevalence of bacteria between tumors (T) and their NAT in breast, lung, and ovary samples. A two-sample proportion z test was used to calculate the P values. Sizes of dots reflect phylotype levels, gradually increasing from species to phylum. Bacteria are colored according to the tumor type (breast, pink; lung, green; and ovary, purple) if they passed significance thresholds (effect size >5%, P value <0.05, and FDR-corrected Q value <0.25).
Metabolic functions encoded by intratumor bacteria are associated with clinical features of certain tumor subtypes

Our results demonstrate that intratumor bacteria span a wide spectrum of the bacterial kingdom. To investigate the functional activities of intratumor bacteria, we used the PICRUSt2 tool (50–52) to map the 16S sequences to the genes and pathways that these bacterial species may harbor (fig. S18 and tables S8 and S9).

Unsupervised clustering analysis of 287 predicted metabolic MetaCyc pathways that showed the greatest variability between the tumor types revealed that certain microbiome metabolic pathways were relatively specific to certain tumor subtypes (Fig. 5A). We found a few tumor typespecific enrichments of bacterial pathways that can degrade metabolites known to be enriched in these same tumor types (table S10). For example, degradation of hydroxyprolines by bacteria (MetaCyc PWY-5159) was enriched in bone tumors (effect size 14.6%, P value <0.01, proportion test). Bone collagen is a main source of hydroxyproline, and many bone pathologies, like bone tumors, have been shown to result in elevated hydroxyproline levels (53). In the case of lung cancer, MetaCyc pathways responsible for the degradation of chemicals in cigarette smoke, such as toluene, acrylonitrile, and aminobenzoates (TOLUENE-DEG-2-OH-PWY, P344-PWY, and PWY-6077), were significantly enriched in bacteria found in lung tumors compared with other tumor types (effect size 8.4, 8, and 7.2%, 4-value <0.001 for all, proportion test).

The enrichment for bacteria with the predicted capability to degrade cigarette smoke metabolites in lung tumors may suggest that high levels of these metabolites create a preferred niche for bacteria that can use these metabolites. To confirm this hypothesis, we compared the bacterial functions found in non-small cell lung cancers (NSCLCs) of 100 current smokers with those in NSCLCs of 43 people who had never smoked (never-smokers). We found that 17 of the 49 MetaCyc pathways that were significantly enriched in tumors of current smokers were pathways that degrade chemicals found in cigarette smoke, such as nicotine, anthranilate, toluene, and phenol (Fig. 5B, blue circles, and table S11). We also found eight MetaCyc pathways related to the biosynthesis of metabolites that can be used by plants—for example, for the biosynthesis of glycine, a key intermediate in plant photosynthesis (Fig. 5B, red circles, and table S11). We speculate that some plant-associated bacteria, or their DNA, are present in cigarette tobacco and are thus enriched in the lung tumors of smokers.

To determine which bacteria contribute to the MetaCyc pathways that are enriched in the lung tumors of current smokers, we compared the proportion of all bacterial taxa found in...
lung tumors of current smokers (n = 100) with those in the tumors of never-smokers (n = 43). We found that most of the enriched taxa in the lung tumors of smokers belong to the Proteobacteria phylum. However, none of these bacteria reached significance after correction for multiple-hypothesis testing (Fig. 5C and table S12), which indicates that there was no homogeneous population of species conferring this functionality across samples. We reasoned that, although bacterial ecology differs between tumors, there is a shared functional signal related to the specific environment within the lungs of smokers. We were able to demonstrate that a very large number of heterogeneous bacteria contribute to the degradation functions of cigarette smoke metabolites and the biosynthesis of plant metabolites (Fig. 5D). Bacteria expressing these functions are found mainly in the Proteobacteria, Actinobacteria, and Cyanobacteria phyla, and they are depleted from the Firmicutes phylum (Fig. 5D).

We also found selective enrichment of bacterial functions in certain tumor subtypes. For example, multiple MetaCyc pathways were enriched in bacteria from 270 ER+ breast tumors compared with 49 ER− breast tumors (Fig. 5E and table S13). The most significantly enriched pathways in bacteria within ER+ breast tumors were arsenate detoxification and mycothiol biosynthesis. Arsenic is a Group 1 carcinogen that can increase the risk of breast cancer (54) and has been shown to induce expression of the estrogen receptor in human breast cancer (55). Mycothiol is used by bacteria to detoxify reactive oxygen species (56). Because ER+ breast tumors are known to have increased reactive oxygen species (35), the estrogen receptor in human breast cancer (58) may influence the development of cancer or whether their presence is associated with specific microbial signatures. This is consistent with a recent publication that demonstrated that reexamination of whole-genome and whole-transcriptome sequencing data from The Cancer Genome Atlas (TCGA) for microbial sequences identified associations between different cancer types and specific microbiota (19). Extending our analysis to the functional level demonstrated that, despite a very large variation in taxa levels, certain tumor environments are enriched for common, relevant bacterial functional traits. This observation is somewhat analogous to the relative stability of the human gut microbiome functions compared with its microbial taxa (58, 59). Using multiple visualization methods and culturalomics, we were able to validate the presence of bacteria in the tumors and demonstrate their intracellular localization in both cancer and immune cells.

Our data do not establish whether intratumor bacteria play a causal role in the development of cancer or whether their presence simply reflects infections of established tumors (60, 61). As tumors develop, their disorganized, leaky vasculature may allow circulating bacteria to enter, and the immunosuppressed environment may provide a refuge for them (61, 62). Intratumor bacteria may also arise from the NAT, which can explain the high similarity we found between the tumor microbiome and its NAT microbiome. Whether or not bacteria play a causal role in tumorigenesis, it is of interest to further explore the effects that intratumor bacteria may have on different phenotypes of cancer cells and on the immune system and its interactions with tumor cells. Just as manipulation of the gut microbiome has been shown to affect the response of tumors to immune-checkpoint blockade therapy (23–25, 28), we speculate that manipulation of the tumor microbiome may also affect tumor immunity and the response to immune therapy. Thus, better understanding of these effects may pave the way for novel treatment options for cancer patients.

A.P.C. is supported by the Cancer Prevention and Research Institute of Texas Research Training Program (RP170067). **Author contributions:** D.N., I.L., G.F., N.S., and R.St. conceived and initiated the project and performed most of the data analysis. I.L., G.F., and O.G. wrote data analysis code. D.N., N.G., and Y.Z. performed staining experiments. D.N., I.L., and T.A. generated GraphPhlAn analysis. T.Da. and S.L.-Z. performed CLEM experiments. R.St., D.N., I.L., and N.S. wrote the initial manuscript. G.F., N.G., and Y.Z. helped with preparations of the manuscript. J.S., I.K., V.G., S.A., G.P., M.R., Z.A.C., R.A., A.P.C., M.A.W.K., G.O., K.B.-S., S.H., T.S., E.A.R., C.U.B., A.R., R.Sh., A.A., T.Do., R.K., Z.R.C., E.N.G.-Y., E.Y.-S., H.S., N.B., A.B.-N., B.K., A.N., T.G., M.D., K.L., J.B., S.Y.-K., I.B., D.S.P., R.W., J.A.W., and D.J.R. provided patient samples. J.S. and G.M. helped with pathological analysis. R.St. supervised the project. **Competing interests:** R.St. received a grant from Merck EMD Serono and is a paid adviser to Biomica and BiomX. R.St., N.S., and D.N. are inventors on a U.S. provisional patent application (63/005,540) submitted by Yeda Research and Development, the Weizmann Institute of Science. J.A.W. and V.G. are inventors on a U.S. patent application (PCT/US17/53,717) submitted by the University of Texas MD Anderson Cancer Center that covers methods for transforming bacterial species into functions using PICRUSt 2. G.M. and G.F. are inventors on a U.S. patent application (PCT/US17/53,717) submitted by the University of Texas MD Anderson Cancer Center that covers methods for transforming bacterial species into functions using PICRUSt 2. The human tumor microbiome is composed of tumor type–specific intracellular bacteria

**Profiling tumor bacteria**

Bacteria are well-known residents in human tumors, but whether their presence is advantageous to the tumors or to the bacteria themselves has been unclear. As an initial step toward addressing this question, Nejman *et al.* produced an exhaustive catalog of the bacteria present in more than 1500 human tumors representing seven different tumor types (see the Perspective by Atreya and Turnbaugh). They found that the bacteria within tumors were localized within both cancer cells and immune cells and that the bacterial composition varied according to tumor type. Certain biologically plausible associations were identified. For example, breast cancer subtypes characterized by increased oxidative stress were enriched in bacteria that produce mycothiol, which can detoxify reactive oxygen species.
